# Assignment 2 Group 26

Vanshita Sharma Kumar Lucian Truşcă Xander Poortvliet 2025-10-10

### Excercise 2.1

#### 2.1a

We first will start with the full multi-regression model

```
model_full = lm(total ~ expend + ratio + salary + takers, data=sat)
```

```
## The AIC score for the full model = 497.3694
```

Step Up method: With the forward selection we will first start with no predictors and add variables one by one based on the lowest AIC

```
model_StepUp = lm(total ~ expend + takers, data=sat)
```

```
## The AIC score for the step-up method = 494.7994
```

Step-down Method: we start from the full model and iteratively remove variables that worsen AIC the least.

```
model_StepDown <- lm(total ~ expend + takers, data=sat)</pre>
```

## The AIC score for the step-down method = 494.7994

Model interpretation: SAT performance is best explained by school spending and participation rate. Other variables (ratio, salary) don't significantly improve model fit.

### 2.1b

Where the result for the AIC is 473.9 (rounded up from 473.85).

```
## [1] 473.8576

## The AICS without takers2 is: 494.7994

## Analysis of Variance Table
##
## Model 1: total ~ expend + takers
## Model 2: total ~ takers + takers2 + expend
## Res.Df RSS Df Sum of Sq F Pr(>F)
## 1 47 49520

## ---
## Signif. codes: 0 '***' 0.001 '**' 0.05 '.' 0.1 ' ' 1
```

In a nested-model ANOVA comparing  $M_1$ : total  $\sim$  expend+takers to  $M_2$ : total  $\sim$  expend+takers+takers<sup>2</sup>, adding the quadratic term reduces the residual sum of squares from 49,520 to 31,298, a drop of 18,222 with one additional parameter (df = 1), yielding F(1,46) = 26.783 and  $p = 4.872 \times 10^{-6}$ . This highly significant improvement leads us to reject  $H_0$ :  $\beta_{\text{takers}^2} = 0$  and conclude that  $\text{takers}^2$  is a useful predictor: it captures curvature in the relationship between SAT scores and participation that the linear-only specification misses.

#### 2.1c

Comparing the reduced model  $M_1$  to the expanded model  $M_2$ , the ANOVA shows a large and statistically significant drop in residual sum of squares as seen previously, where this drop implies the rejection of  $H_0: \beta_{\text{takers}^2} = 0$  and confirming that the quadratic term is informative; this statistical improvement is mirrored by information criteria, with AIC falling from  $\approx 492.8$  for  $M_1$  to  $\approx 471.9$  for  $M_2$ , indicating that the model including takers<sup>2</sup> provides a substantially better fit despite its extra parameter.

#### 2.1d

QUESTION D

### Excercise 2.2

### 2.2a

```
data$type <- factor(data$type)
model_a = lm(volume ~ type, data = data)

             1
## Residuals 57 11394.8 199.91
```

A one-way ANOVA comparing mean wood volume between Beech and Oak trees (n = 59) found no statistically significant difference in average volume between the species (F = 1.90, p = 0.17); thus, based on these data, we cannot conclude that Oaks are more voluminous than Beeches at the 5% significance level. The estimated mean volumes were approximately  $\bar{V}_{\text{Oak}} \approx$  [insert mean] and  $\bar{V}_{\text{Beech}} \approx$  [insert mean]; although Oaks appear slightly larger on average, this observed difference is not statistically significant.

### 2.2b

```
data$type = factor(data$type)
model_b <- lm(volume ~ diameter + height + type, data = data)</pre>
summary(model_b)

As  $p \le 0.05$ , this yields a better result.

# Excercise 2.3

To solve the problem of the optimal product mix with excel. We choose the number of servings of each food to minimize total cost while meeting minimum nutrient requirements. It is important to note that for all questions, the options menu has the same configuration as in the image below.

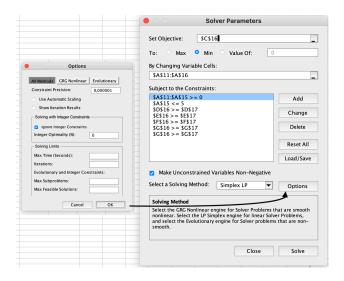

Figure 1: Options Menu

# Notation

- Foods  $F = \{\text{carrots}, \text{potatoes}, \text{bread}, \text{cheddar}, \text{pb}\}.$
- Parameters per serving  $f \in F$ :
  - price  $c_f$ ,

  - calories  $a_f^{\text{cal}}$ , fat  $a_f^{\text{fat}}$ , protein  $a_f^{\text{prot}}$ , carbs  $a_f^{\text{carb}}$ .
- Minimum requirements:  $(b_{\rm cal},b_{\rm fat},b_{\rm prot},b_{\rm carb})=(2000,50,100,250).$
- Decision variables:  $x_f \ge 0 = \text{servings of food } f$ .

### 2.3a

The solution uses continuous servings, so constraints can be met exactly. We can visualise our excel solver.

$$\begin{split} & \min_{x \geq 0} & \sum_{f \in F} c_f \, x_f \\ & \text{s.t.} & \sum_{f \in F} a_f^{\text{cal}} x_f \; \geq \; b_{\text{cal}}, \\ & \sum_{f \in F} a_f^{\text{fat}} x_f \; \geq \; b_{\text{fat}}, \\ & \sum_{f \in F} a_f^{\text{prot}} x_f \; \geq \; b_{\text{prot}}, \\ & \sum_{f \in F} a_f^{\text{carb}} x_f \; \geq \; b_{\text{carb}}. \end{split}$$

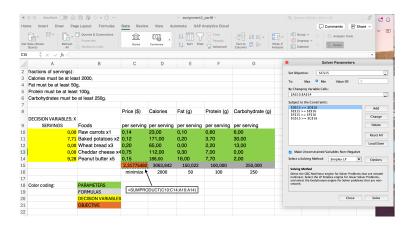

Figure 2: 2.3a Excel Solver

The optimal continuous solution selects **7.7147** servings of potatoes and **9.2800** servings of peanut butter, with **0** servings of carrots, bread, and cheddar; the **total cost is \$2.3178**. The **binding constraints are protein and carbohydrates**, while **calories** ( $\approx 3063.8$ ) and **fat** ( $\approx 150.0$  g) have slack.

### 2.3b

Let pean ut butter be split into two variables:  $x_{\rm pb}^{(1)}=$  the **first** (cheap) PB servings, and  $x_{\rm pb}^{(2)}=$  any **additional** PB servings. Prices:  $c_{\rm pb}^{(1)}=0.15,$   $c_{\rm pb}^{(2)}=0.25.$  Cap:  $0\leq x_{\rm pb}^{(1)}\leq 5.$ 

All nutrients per serving are identical for both PB tiers.

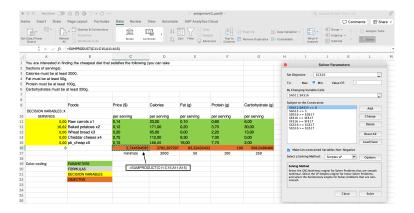

Figure 3: 2.3b Excel Solver

Interpretation. This stays linear by replacing PB with two variables: buy up to 5 cheap units, then any extra at the higher price. In the optimum, the model purchases exactly the 5 cheap PB units and substitutes the rest with the next-best cheap source (potatoes), increasing total cost to 16.62 vs. (a).

### 2.3c

Same as (a), but restrict servings to integers:

$$x_f \in \mathbb{Z}_{\geq 0}$$
 for all  $f \in F$ .

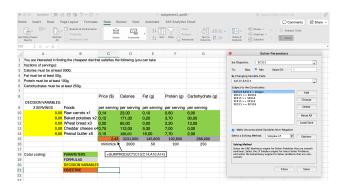

Figure 4: 2.3c Excel Solver

*Interpretation.* Integrality removes the ability to hit thresholds exactly, so the solution "rounds up" and typically costs more than the fractional LP.

# Excercise 2.4

## 2.4a

This model minimizes total shipping cost from three sources (S1–S3) to four destinations (D1–D4). Each source has a *supply limit* and each destination has a *demand requirement*. The Solver chooses shipments  $x_{ij}$  (from source i to destination j) so that **total cost is minimal** while all supply and demand constraints are met.

Model.

$$\begin{split} & \min_{x} \quad \sum_{i \in S} \sum_{j \in D} c_{ij} \, x_{ij} \\ & \text{s.t.} \quad \sum_{j \in D} x_{ij} \, \leq \, a_{i} \quad \forall i \in S \quad \text{(supply)} \\ & \quad \sum_{i \in S} x_{ij} \, \geq \, b_{j} \quad \forall j \in D \quad \text{(demand)} \\ & \quad x_{ij} \, \geq \, 0 \qquad \quad \forall (i,j) \in S \times D \; . \end{split}$$

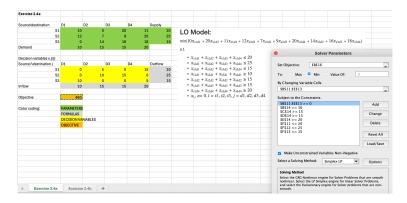

Figure 5: 2.4a Excel Solver

The optimal flows is the following, S1 ships 5 to D2 and 15 to D4; S2 ships 10 to D3 and 15 to D2; S3 ships 10 to D1 and 5 to D4. With a minimum total transportation cost of \$460. Interpretation. The solution uses the cheapest lanes as much as possible (e.g.,  $S2\rightarrow D2$ ,  $S3\rightarrow D1$ ) and avoids expensive ones (e.g.,  $S1\rightarrow D3$ ). Total cost \$460 is the most economical plan that exactly meets demand without exceeding supply.

#### 2.4b

Question 2.4b extends the previous question by adding a fixed cost of 100 each time a route (i, j) is used. Binary variables  $y_{ij} \in \{0, 1\}$  indicate whether a route is opened. The objective now minimizes transport cost + fixed activation cost.

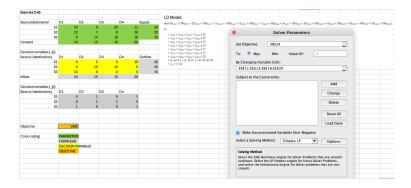

Figure 6: 2.4b Excel Solver

The optimal plan opens only cost-effective routes (those with  $y_{ij} = 1$ ) and sends the required flows on them. The minimum total cost (including fixed charges) will be \$1060. Interpretation. With activation costs, the model prefers fewer routes carrying larger volumes to avoid paying many fixed fees. This raises total cost from \$460 to \$1060, but yields a more consolidated network.
